Field data-based evaluation of methods for recovering surface wave elevation from pressure measurements

A. Mouragues, P. Bonneton, D. Lannes, B. Castelle, V. Marieu

Abstract

We compare different methods to reconstruct the surface elevation of irregular waves propagating outside the surf zone from pressure measurements at the bottom. The traditional transfer function method (TFM), based on the linear wave theory, predicts reasonably well the significant wave height but cannot describe the highest frequencies of the wave spectrum. This is why the TFM cannot reproduce the skewed shape of nonlinear waves and strongly underestimates their crest elevation. The surface elevation reconstructed from the TFM is very sensitive to the value of the cutoff frequency. At the individual wave scale, high-frequency tail correction strategies associated with this method do not significantly improve the prediction of the highest waves. Unlike the TFM, the recently developed weakly-dispersive nonlinear reconstruction method correctly reproduces the wave energy over a large number of harmonics leading to an accurate estimation of the peaked and skewed shape of the highest waves. This method is able to recover the most nonlinear waves within wave groups which some can be characterized as extreme waves. It is anticipated that using relevant reconstruction method will improve the description of individual wave transformation close to breaking.

1. Introduction

Pressure sensors have long been used to measure waves in the coastal zone mainly because of their robustness, low-cost aspect and convenience to deploy. However, they do not provide direct measurement of the wave surface elevation. The widely-used method to reconstruct the wave surface elevation from pressure measurements at the bottom is the so-called transfer function method (TFM; e.g. Bishop and Donelan, 1987), based on the linear wave theory. The TFM allows to recover linear wave fields and gives a reasonable estimate of the significant wave height (i.e. wave energy). Guza and Thornton (1980) found that the total harmonic variance could be retrieved with error of 7.6% near the breakpoint. However, for the highest frequencies, the energy density spectra reconstructed from the TFM blows up. To prevent the latter, a cutoff frequency is commonly used (e.g. Lee and Wang, 1985; Bishop and Donelan, 1987). Contrary to what is generally accepted in the literature for swell reconstruction, the need for such a cutoff is mainly due to wave nonlinearities rather than to pressure measurement noise (Bonneton and Lannes, 2017). In this paper, we will show that the cutoff frequency is artificial and that the TFM solution is very sensitive to its value.

In shallow water, nonlinear interactions induce the development of high-frequency harmonics which cannot be correctly reproduced by the TFM. Martins et al. (2017a) found that the TFM fails to recover the peaked and skewed shape of nonlinear waves with individual wave height error up to 30%. However, well predicting nonlinear waves, especially in the shoaling zone, is of paramount importance for many coastal applications. Indeed, the most nonlinear waves are very often found to be the largest waves. An accurate prediction of these waves is then essential for applications involving extreme wave events, wave submersion studies, or coastal construction projects that need to cope with the height of the most extreme waves. Moreover, an accurate characterization of wave skewness and asymmetry is essential for studying sediment transport (Dubarbier et al., 2015). Lastly, the surface wave reconstruction is also crucial for the calibration of phase-averaged wave model parameters (e.g. Booij et al., 1999) and for the validation of phase-resolving wave models (e.g. Zijlema et al., 2011; Bonneton et al., 2011).

In the present paper, we review and apply the main methods designed to reconstruct in situ irregular waves. First, we present the commonly-used linear methods as well as recently developed nonlinear methods. Different high-frequency tail correction procedures associated with the TFM are also reviewed. Then, we apply and compare each method with field data, in terms of spectral and temporal parameters, in...
near-breaking conditions. In such conditions, wave groups contain highly nonlinear waves for which the use of the TFM, based on the linear wave theory, is questionable. More importantly, these waves need to be properly described as they control the break point position and can be characterized as extreme waves. Finally, we conduct a wave-by-wave analysis of the whole dataset in order to compare each method over a large range of nonlinearities.

2. Reconstruction methods

In this section, the main methods to reconstruct irregular surface wave elevation from in situ pressure measurements at the bottom are reviewed. We focus on unbroken waves propagating outside the surf zone in intermediate to shallow water depth, for which the flow can be assumed irrotational. In this work, the bottom variation contribution is assumed negligible, which is true for many coastal applications. The background current contribution is also assumed negligible, which is true for most wave-dominated coastal areas far from river mouths or tidal inlets. Bonneton and Lannes (2017) derived a reconstruction formula which takes into account a background current. However, their method requires additional velocity measurement, which, in most nearshore field campaigns, is rarely collected at the same location as the pressure sensor, and is therefore out of scope of the present paper.

Three main length scales are critical to the problem addressed here: the wave amplitude $a$, the characteristic horizontal length scale $L$ (in the typical wave number) and the mean water depth $h_0$. The wave propagation is then controlled by two dimensionless parameters:

$$\varepsilon = \frac{a}{h_0}, \quad \mu = \left(\frac{h_0}{L}\right)^2 = (kh_0)^2,$$

where $\varepsilon$ is a nonlinearity parameter and $\mu$ is a shallowness (or dispersion) parameter; or alternatively the steepness parameter $\sigma$:

$$\sigma = \frac{a}{L} = \sqrt{\mu}.$$

From a practical point of view, deep water cases ($\mu > 1$) are disregarded as pressure measurements are not relevant in such water depths. Reconstruction methods are usually based on an asymptotic expansion of the irrotational wave equations in terms of the steepness parameter $\sigma$, which is a small parameter for most coastal waves. The small steepness regime encompasses the two following scenarios: large amplitude waves ($\varepsilon \sim 1$) in shallow water ($\mu < 1$) and small amplitude waves ($\varepsilon < 1$) in intermediate depth ($\mu \sim 1$).

For the sake of clarity, a two-dimensional wave field associated with the Cartesian coordinates $(x,z)$ is considered, where $x$ corresponds to the horizontal axis along which waves propagate and $z$ is the positive-upward vertical axis (see Fig. 1). The mean water level and the free surface elevation are defined by $z = 0$ and $z = \zeta(x,t)$, respectively. The pressure sensor is located at a distance $\delta_m$ from the bottom level $z = -h_0$, and provides the measured pressure $p_m(t) = p(z = -h_0 + \delta_m, t)$.

For very long waves (very small $\mu$), the surface elevation can be estimated from the hydrostatic equilibrium. The hydrostatic reconstruction elevation, $\zeta_{hs}^m$, is then given by:

$$\zeta_{hs}^m(t) = \frac{p_m(t) - p_0}{\rho g} + \delta_m - h_0,$$

where $p_0$ is the constant atmospheric pressure, $\rho$ is the water density and $g$ is the gravity. This hydrostatic reconstruction (Eq. (3)) gives good results for tides and tsunamis, but cannot be applied to wind waves which have non-hydrostatic characteristics. Some of the most commonly-used non-hydrostatic linear reconstruction methods are introduced below, and the recently developed nonlinear approaches are further presented.

![Fig. 1. Definition sketch of the physical variables. $x$ and $z$ are the horizontal (wave propagation axis) and vertical axis, respectively. $z = 0$ is the mean water level and $-h_0$ is the constant bottom elevation. $\zeta(x,t)$ is the surface wave elevation, $a$ is the characteristic wave amplitude and $\delta_m$ represents the distance from the bottom where the pressure sensor is located.](image-url)

\[ T_F[\{\xi\}(k, t)] = K_F(k)T_F[\{\eta_{hi}\}(k, t)] \]  
\[ K_F(k) = \frac{\cosh(kh_0)}{\cosh(k\delta_m)} \]  
\[ \omega^2 = g k \tanh(kh_0), \]

where \( K_F \) is the non-hydrostatic correction factor.

Eqs. (13) and (16) are hereafter referred to as the linear formula in space, and the resulting reconstructed surface elevation is hereafter referred to as \( \eta_{\text{space}} \) (see linear formula in space in Table 1). In Fig. 2, \( \eta_{\text{space}} \) is compared to the surface elevation computed from the Full Euler equations (Fenton, 2014) in case of a periodic weakly nonlinear wave \( \epsilon = 0.15, \mu = 0.25 \). The linear formula in space significantly improves the hydrostatic reconstruction in terms of crest elevation and wave shape, even if the crest elevation is still underestimated compared to the Full Euler solution.

2.1.2. Transfer function method

The linear formula (Eqs. (13) and (14)) involves a Fourier transform in space, which increases rapidly with the harmonics and leads to a blow up of the energy density overestimation, even for weakly nonlinear waves, as described by Bonneton and Lannes (2017), it is due to secondary harmonics which are phase locked, or bound, to the fundamental harmonics and travel at a celerity which is much larger than their intrinsic (linear) phase speed. Thus, the linear dispersive relation (Eq. (17)) strongly overestimates the wave number of the harmonics leading to the overestimation of \( K_F \) (Eq. (16)).

To overcome this TFM problem, the commonly-used approach is to introduce a cutoff frequency \( f_c \). At \( f = f_c \), the TFM spectrum is truncated and replaced by the hydrostatic spectrum for \( f > f_c \) (equivalent to a low-pass filter). The expression of \( K_F \) then becomes:

\[ K_F(\omega) = \frac{\cosh(kh_0)}{\cosh(k\delta_m)} \text{ for } \frac{\omega}{2\pi} \leq f_c \]

\[ \mathcal{F}_T[f](\omega) = \int_{-\infty}^{\infty} f(t)e^{-i\omega t} \, dt. \]

Bonneton and Lannes (2017) showed that this method is mathematically justified for linear wave fields but is questionable when applied to nonlinear waves. This is illustrated with the periodic weakly nonlinear wave field presented in Fig. 2. The surface elevation computed from the TFM is hereafter referred to as \( \eta_{\text{NC}} \) (Eqs. (15)-(17); see TFM - no cutoff in Table 1). Fig. 3 shows that the energy density of the two first harmonics is well predicted by \( \eta_{\text{NC}} \), while the energy density of the following harmonics are underestimated.

Unlike the linear formula in space, the TFM (see \( \eta_{\text{NC}} \) in Fig. 3) leads to an energy density overestimation, even for weakly nonlinear waves, which increases rapidly with the harmonics and leads to a blow up of the TFM solution (overestimation of the fifth harmonic by two orders of magnitude). As described by Bonneton and Lannes (2017), it is due to secondary harmonics which are phase locked, or bound, to the fundamental harmonics and travel at a celerity which is much larger than their intrinsic (linear) phase speed. Thus, the linear dispersive relation (Eq. (17)) strongly overestimates the wave number of the harmonics leading to the overestimation of \( K_F \) (Eq. (16)).

Full Euler solution (black circle); hydrostatic reconstruction: \( \eta_{hi} \) (blue line); linear formula in space: \( \eta_{\text{space}} \) (magenta dashed line); see the associated equations in Table 1. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

Fig. 3. Surface elevation energy density spectra \( E(n) \) of a periodic weakly nonlinear wave, \( \epsilon = 0.15, \mu = 0.25, \delta_m = 0 \). Full Euler solution (black circle); hydrostatic reconstruction: \( \eta_{hi} \) (blue crosses); linear formula in space: \( \eta_{\text{space}} \) (magenta crosses); TFM - no cutoff: \( \eta_{\text{NC}} \) (green circles); TFM - sharp cutoff: \( \eta_{\text{sh}} \) (green crosses); see the associated equations in Table 1. The cutoff harmonic index is indicated by the vertical black dotted line. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)
$K_p(\omega) = 1 \quad \text{for} \quad \frac{\omega}{2\pi} > f_c$.

Eq. (20) is hereafter referred to as the sharp cutoff and the associated surface elevation is referred to as $\zeta_{\text{SH}}$ (see TFM - sharp cutoff in Table 1).

It is worth noting that contrary to what is generally accepted in the literature for swell reconstruction, the need for such a cutoff is mainly due to wave nonlinearities rather than to pressure measurement noise. Therefore, $f_c$ can be considered as a nonlinear cutoff frequency. Nonetheless, in most coastal applications, two different empirical approaches are generally used to determine the value of $f_c$ (Smith, 2002).

The first one consists in setting $f_c$ at the frequency where the pressure signal is one order of magnitude higher than the noise floor, which is questionable. In the second approach, $f_c$ is set to the frequency where $K_p$ is less than 10 to 1000, which value depends on the pressure sensor resolution (Wolf, 1997). The reconstructed wave characteristics are very sensitive to the subjective value of $f_c$ (see Section 4.1.1; Smith, 2002; Jones and Monismith, 2007). In Fig. 3, the value of $f_c$ is optimized i.e. we set $f_c$ by comparing the wave energy reconstructed by the TFM with no nonlinear cutoff frequency, $\zeta_{\text{NC}}$ (see TFM - no cutoff in Table 1), and the true wave energy. $f_c$ is taken at the frequency where $\zeta_{\text{NC}}$ starts to overestimate the true wave energy (i.e. where $K_p$ is too high), here after the second harmonic (see the vertical dashed line in Fig. 3).

In most studies, the direct measurement of the surface wave elevation is not available but is retrieved from pressure measurements and $f_c$ cannot be optimized objectively. Most of the time, it is not clear how the cutoff frequency has been set and, for field applications, its value typically ranges between 0.25 and 0.6 Hz (e.g. Guza and Thornton, 1980; Russink et al., 1998; Smith, 2002; Sénéchal et al., 2004). However, the way $f_c$ is set is crucial and can strongly affect the wave shape. Indeed, the cutoff induces spectral information loss beyond $f_c$ that will generate oscillations within the reconstructed time series (see Section 4.1.1). The frequency of these oscillations being of the same order as $f_c$, those are then strongly dependent on the cutoff and are not physical. This kind of oscillations is hereafter referred to as parasite oscillations.

2.1.2.1. High-frequency tail empirical correction. As introduced above, the widely-used TFM requires a cutoff frequency. Using the sharp cutoff method (Eq. (20); see TFM - sharp cutoff in Table 1) will induce spectral information loss for $f > f_c$ (see Fig. 3). To limit this loss of information, several empirical formula were derived to artificially fill the high-frequency tail. Three empirical methods are presented here.

A first method is to replace the high-frequency tail by a Jonswan diagnostic tail. The energy density spectra $E(f)$ is expressed as a function of $f^{-n}$ where $n$ represents the tail’s slope (Eq. (21); see TFM - Jonswan in Table 1):

$$E(f > f_c) = E(f_c) \left(\frac{f}{f_c}\right)^{-n}.$$  

(21)

The value of $n$ depends on the water depth. $n = 5$ is usually set in deep water while $n = 4$ and $n = 3$ are set for intermediate water and shallow water, respectively.

Eq. (21) allows to better predict spectral wave parameters (e.g. Wolf, 1997; Smith, 2002; Jones and Monismith, 2007). However, this method is not able to recover surface elevation time series as the phase signal is not given by this approach.

The two other methods consist in tuning the value of $K_p$ beyond $f_c$. Neumeier uses an empirical correction factor $K_p$ which linearly decreases over an artificial frequency range (Eqs. (22) and (23); see TFM - linear cutoff in Table 1).

$$K_p(\omega) = K_p, L \quad \text{for} \quad \frac{\omega}{2\pi} < f_c, \quad \text{for} \quad \frac{\omega}{2\pi} > f_{\text{in}},$$  

(22)

where the expression of $K_p, L$ and $f_{\text{in}}$ can be found in Neumeier.

A steady correction factor can also be applied (Eq. (24); see TFM - steady cutoff in Table 1). The correction factor beyond $f_c$ is taken as $K_p(\omega = 2nf_c)$ and stays the same over the whole high-frequency tail.

$$K_p(\omega) = K_p(\omega = 2nf_c) \quad \text{for} \quad \frac{\omega}{2\pi} > f_c.$$  

(24)

In Section 4.1.1, the influence of the above high-frequency tail correction methods on wave reconstruction and parasite oscillations will be addressed. A sensitivity study over the typical in situ $f_c$ range will also be conducted.

2.2. Semi-empirical transfer function method

To avoid introducing a cutoff frequency, several authors have proposed local methods, as opposed to global (spectral) methods, in order to improve the shape and height of individual waves. Nielsen (1986) was the first to develop such methods called local sinusoidal approximation (LSA) methods.

A local frequency based on the local curvature is defined as:

$$\omega_{i+1}^2 = \left(\frac{\zeta_{i+1}^H}{\zeta_{i}^H}\right) = -2\left(\frac{\zeta_{i+1}^m}{\zeta_{i}^m}\right) + \left(\frac{\zeta_{i+1}^m}{\zeta_{i}^m}\right)^2 \Delta \zeta^2$$

(25)

where $\left(\frac{\zeta_{i+1}^m}{\zeta_{i}^m}\right)$ is the $i$th value of time series $\zeta_{i}^m$ (Eq. (3)) and $\Delta \zeta = \frac{\zeta_{i}^m - \zeta_{i+1}^m}{\Delta t}$ being the sampling rate.

Along with a stretched linear theory, Nielsen (1986) established the following semi-empirical transfer function method (see semi-empirical TFM in Table 1):

$$\zeta_{i}^H = \zeta_{i}^m F \left[\frac{\omega_{i+1}^2}{\Delta \zeta} (h_0 + \zeta_{i}^m - \delta_i)\right]$$

(26)

where the transfer function $F$ is fitted as $F(x) = \exp \left(\frac{A}{2} x \right)$ and the empirical factor $A$ is given by $A = \frac{4}{\delta_i} = 0.64 + 0.5 \frac{\delta_i}{h_0}$. Fenton (1987) introduced local polynomial approximation (LPA) methods in which the complex velocity potential and the surface elevation are given by polynomials and incorporated into the fully nonlinear equations of motion. Townsend and Fenton (1997) compared both LSA and LPA and concluded that LSA (Eq. (26)) performs better than LPA especially for low $\delta_i/h_0$ ratio. Moreover, LSA requires less computational effort than LPA (Nielsen, 1989; Townsend and Fenton, 1997). Therefore, only the LSA method from Nielsen (1989) is considered in this study.

2.3. Nonlinear methods

Over the past few years, several authors have gone to great lengths studying nonlinear surface wave reconstruction from pressure measurements (e.g. Deconinck et al., 2012; Oliveras et al., 2012; Constantin, 2012; Clamond and Constantin, 2013). Nevertheless, all these methods were derived assuming steady water waves propagating at a constant celerity and are therefore not suitable for real coastal applications.

However, Oliveras et al. (2012) derived a heuristic reconstruction method $\zeta_{\text{HE}}$ as a function of $\zeta$ (here, $\zeta$ is the surface elevation reconstructed from the linear formula in space or from the TFM) that can be applied for irregular waves travelling at different wave celerities. For $\delta_i = 0$ (see Vasan and Oliveras, 2017 if $\delta_i > 0$), $\zeta_{\text{HE}}$ is written as follows:

$$\zeta_{\text{HE}} = 1 - \frac{1}{\tau} \frac{\zeta}{\kappa \sinh(k h_0 \tau_f)}$$

(27)

where $k$ is computed with the dispersion relation (Eq. (17)).
As remarked in Bonneton and Lannes (2017), at order \(O(\epsilon)\), this formula is equivalent to:

\[
\zeta_{\text{HE}} = \zeta_L - \frac{1}{g} \frac{\partial}{\partial t} \delta_1 \zeta_L.
\]

(28)

Using data from laboratory experiments, the heuristic method was found to significantly improve the wave crest elevation as well as the wave shape compared to the TFM (Oliveras et al., 2012).

Recently, Bonneton and Lannes (2017) and Bonneton et al. (2018) have derived nonlinear reconstruction methods also suitable for irregular waves. Bonneton and Lannes (2017) performed an asymptotic expansion of the nonlinear wave equations in terms of the steepness parameter \(\epsilon\). For \(\delta_m = 0\) (see Bonneton and Lannes, 2017 if \(\delta_m > 0\)) and neglecting the \(O(\epsilon^2)\) terms, they obtained a fully-dispersive nonlinear reconstruction method:

\[
\zeta_{\text{NL}} = \zeta_L - \frac{1}{g} \frac{\partial}{\partial t} \delta_1 \zeta_L - \frac{1}{g} \frac{\partial}{\partial \xi} (\delta_1 \zeta_L).
\]

(29)

The nonlinear term on the right-hand side of Eq. (29) can be split into two nonlinear terms: (1) \(-\frac{1}{g} \frac{\partial}{\partial t} \delta_1 \zeta_L\) and (2) \(-\frac{1}{g} \frac{\partial}{\partial \xi} (\delta_1 \zeta_L)^2\). Term (1) improves the wave extrema compared to the linear reconstruction \(\zeta_L\) by increasing the crest elevation and flattening the wave trough. Term (2), which is neglected in the heuristic method (see Eq. (28)), amplifies the wave skewness and asymmetry. Both nonlinear methods described above rely on \(\zeta_L\). The latter can theoretically be computed using the linear formula in space \(\zeta_{L,\text{space}}\). Fig. 4 shows the surface elevation reconstructed from the two nonlinear methods using the linear formula in space \(\zeta_{\text{HE,space}}\) and \(\zeta_{\text{NL,space}}\), respectively; see Table 2.

Both nonlinear methods accurately reproduce the crest elevation and the wave shape. Nonetheless, \(\zeta_{\text{NL,space}}\) provides a better description of the peaked wave shape as well as the crest elevation compared to \(\zeta_{\text{HE,space}}\). As explained in the previous section, the measured pressure \(P_\text{a}\) is often available at one single measurement point which implies to use the classical TFM instead of the linear formula in space. Hence, in practice, a cutoff frequency needs to be introduced for computing \(\zeta_{\text{HE}}\) and \(\zeta_{\text{NL}}\). Bonneton and Lannes (2017) have applied these nonlinear reconstructions in case of fully-dispersive nonlinear bichromatic waves (\(\mu = 0.53\)). Even though the heuristic method is able to properly reproduce the crest elevation, it still underestimates the skewed shape of the largest waves. The fully-dispersive nonlinear method was found to provide a much better description of the peaked and skewed waves than both the TFM and the heuristic reconstructions.

To overcome the need for a cutoff, in weakly-dispersive regime (\(\mu < 1\)), Bonneton et al. (2018) made a Taylor expansion of the nonlinear wave equations with respect to \(\mu\). Neglecting the \(O(\mu^2)\) terms, they obtained the following weakly-dispersive linear and nonlinear reconstruction methods (see Bonneton et al., 2018 if \(\delta_m > 0\)):

\[
\zeta_{\text{HE}} = \zeta_{H,\text{lin}} - \frac{h_0}{2g} \frac{\partial}{\partial t} \zeta_{H,\text{lin}}.
\]

(30)

\[
\zeta_{\text{NL}} = \zeta_{\text{NL,space}} - \frac{1}{g} \frac{\partial}{\partial t} \delta_1 (\zeta_{\text{NL,space}} - \zeta_{\text{NL,space}}^2).
\]

(31)

Along with the semi-empirical TFM (see Table 1), Eqs. (30) and (31) can be applied locally in time and a cutoff frequency is not necessarily needed, unlike for the computation of fully-dispersive methods (TFM, \(\zeta_{\text{HE}}\) and \(\zeta_{\text{NL}}\)). Bonneton et al. (2018) applied Eq. (31) locally in time by discretizating first- and second-order time derivatives involved in Eqs. (30) and (31). Such time discretization requires to filter measurement noise, as with the Fourier approach. However, time derivatives computation is more accurate using Fourier analysis.

In this way, recovering \(\zeta_{\text{NL}}\) and \(\zeta_{\text{NL,space}}\) (and \(\zeta_L\)) still requires a cutoff frequency \(\tilde{f}_{\text{noise}}\) in order to remove pressure measurement noise. However, this cutoff frequency is much higher than the nonlinear frequency \(\tilde{f}_\epsilon\) introduced earlier. Accordingly, \(\zeta_{\text{NL}}\) and \(\zeta_{\text{NL,space}}\) (and \(\zeta_L\)) are computed accounting for much higher frequency spectral information which is crucial to correctly reconstruct the surface elevation of nonlinear waves. Bonneton et al. (2018) found a good agreement for weakly-dispersive nonlinear waves (\(\mu < 0.3\)) between \(\zeta_{\text{NL}}\) and direct \(\zeta\) measurements in case of monochromatic waves (\(\epsilon = 0.65\)), bichromatic waves (\(\epsilon = 0.37\)) and in situ waves (\(\varepsilon_\text{max} = 0.31\) where \(\varepsilon_\text{max}\) is the nonlinear parameter of the highest wave).

3. In situ dataset

3.1. Field site

In order to assess and compare the ability of the reconstruction methods to recover irregular wave field from pressure measurements, in situ hydrodynamic data was collected at La Salie beach, SW France (see Fig. 5). La Salie beach is a relatively alongshore-uniform gently-sloping sandy beach associated with a meso-macro semi diurnal tidal regime. The relatively wide intertidal region (~ 200 m in the cross-shore) allows easy and convenient instrument deployment at low tide.

3.2. Field experiment

The field experiment was carried out over two periods on April 13–14 2017 (LS1) and May 17–18 2018 (LS2) and aimed at characterizing nonlinear waves in intermediate and shallow depth. A Nortek Signature 1 000 kHz current profiler was deployed at low tide. The Signature 1 000 kHz vertical beam allows a high-frequency direct measurement of the surface wave elevation using Acoustic Surface Tracking (AST). Besides AST, it also provides pressure measurements. Signature 1 000 manufacturer (Nortek) reports pressure-derived elevation and AST measurements with accuracy of \(\pm 1\) mm and \(\pm 2\) cm, respectively. The instrument recorded at 8 Hz sampling rate and pressure was measured at 0.7 m above the bottom (\(\delta_m = 0.7\) m). The characteristic bottom slope was \(\phi = 0.015\) at the sensor location.

AST is relatively new ADCP feature that has mainly been validated for waves propagating in deep water (> 20 m) and for sampling rate not exceeding 4 Hz (Pedersen and Nylund, 2004; Pedersen and Lohrmann, 2004). Martins et al. (2017b) collected high-frequency surface elevation measurements and found a very good agreement between the surface elevation measured from the Signature 1 000 kHz and from a LIDAR scanner (root mean square error RMSE of 0.05 m) for an undular tidal bore propagating in the Garonne river (\(\epsilon = 0.08\); \(\mu = 5.85\); the mean water depth at low tide was 2.8 m).

Nonetheless, AST is very sensitive to air bubbles as the acoustic signal can be significantly altered within the water column (see Nortek Signature 1 000 manufacturer (Nortek) reports pressure-derived elevation and AST measurements with accuracy of \(\pm 1\) mm and \(\pm 2\) cm, respectively. The instrument recorded at 8 Hz sampling rate and pressure was measured at 0.7 m above the bottom (\(\delta_m = 0.7\) m). The characteristic bottom slope was \(\phi = 0.015\) at the sensor location.

AST is relatively new ADCP feature that has mainly been validated for waves propagating in deep water (> 20 m) and for sampling rate not exceeding 4 Hz (Pedersen and Nylund, 2004; Pedersen and Lohrmann, 2004). Martins et al. (2017b) collected high-frequency surface elevation measurements and found a very good agreement between the surface elevation measured from the Signature 1 000 kHz and from a LIDAR scanner (root mean square error RMSE of 0.05 m) for an undular tidal bore propagating in the Garonne river (\(\epsilon = 0.08\); \(\mu = 5.85\); the mean water depth at low tide was 2.8 m).

Nonetheless, AST is very sensitive to air bubbles as the acoustic signal can be significantly altered within the water column (see

Hence, the AST ability to provide reliable measurements under wave breaking can be questioned (Pedersen et al., 2002; Birch et al., 2004), but the present study focuses on waves propagating outside the surf zone (see Fig. 6). A video system was set up on the first day of each deployment period to follow the position of the surf zone during the experiment. The system allowed to identify the time evolution of the outer edge of the surf zone, defined as the location of the onset of breaking of the largest waves (see darker points in Fig. 6, within which none of the waves are breaking). The other outer surf zone limits were set by visually checking the AST signal.

Both pressure and AST measurements were divided into 10-min time series. Pressure time series was low-pass filtered (1 Hz) to remove instrumental noise. AST time series was also low-pass filtered to be consistent with pressure time series. The mean water depth $h_0$ was computed from pressure measurements both outside and inside the surf zone. Each water depth time series was detrended to remove tidal variation. The water level was slowly fluctuating with the infragravity motion. We then define the free surface elevation (in the short-wave frequency band) as:

$$\zeta(t) = h(t) - h_{init}(t),$$  (32)

where $h$ is the water depth and $h_{init}$ is the water depth computed over the infragravity frequency range (0.005 Hz - 0.05 Hz). Eq. (32) was applied to both pressure and AST measurements yielding the hydrostatic surface elevation $\zeta_{st} = \zeta_{st}$ (Eq. (3)) and the direct measurement of the surface elevation $\zeta_{AST}$, respectively.

Outside the surf zone, $h_0$ ranged from 2.25 m to 3.72 m (see Fig. 6a). For such water depths, we choose to take $n = 4$ (as in Jones and Monismith (2007)) for the TFM-Jonswap method (Eq. (21)). Except for $h_0$, parameters in Fig. 6 were calculated using $\zeta_{st}$ inside the surf zone and using $\zeta_{AST}$ outside the surf zone. Both experiments were characterized by long and grouped wave conditions with a sea-swell significant wave height $H_{s,short-wave}$ ranging from 0.54 m to 1.08 m (see Fig. 6b) associated with a peak period $T_p$ ranging from 8.6 s to 11.5 s (see Fig. 6c). The maximum observed wave height was 1.54 m for LS1 and 1.95 m for LS2. The wave number $k$ was estimated using the linear dispersion relation (Eq. (17)) yielding the shallowness parameter $\mu = (kh_0)^2$. The whole dataset features relatively small $\mu$ ($\mu \leq 0.2$; see Fig. 6d) characterizing a weakly-dispersive wave regime. It is worth noting that, the parameter $\mu h_0$ being very small for the whole experiment, the bottom contribution can be neglected (Bonneton et al., 2018).

### 3.3. Data processing

#### 3.3.1. AST processing

Even outside the surf zone, the AST signal was sometimes altered by reflection within the water column. This was caused by the presence of air bubbles that were generated by wave breaking occurring shoreward but close to the instrument, which were occasionally moved by currents above the instrument. This led to the presence of spikes in the surface wave elevation time series that were removed using a gradient threshold between two consecutive points.

---

3.3.2. Wave-by-wave analysis

Zero crossing analysis is the most traditional method to determine individual wave characteristics. It first consists in identifying individual waves between each zero-downcrossing or each zero-upcrossing of surface wave elevation. Wave crests and troughs are then respectively defined as the maximum and minimum of surface elevation between two consecutive crossings. In intermediate depth to shallow water, low-frequency motions can be strong and might potentially lead to crests under the mean sea level and troughs above the mean sea level, making the zero-crossing method irrelevant. In addition, filtering-out low-frequency motions is not a reliable option as it can critically transform the wave extrema and the wave shape (Power et al., 2010). A different method based on a local maxima analysis was implemented (Power et al., 2010; Power et al., 2015; Martins et al., 2017a). A wave is identified between two consecutive crests. The wave trough is taken as the minimum of the surface elevation between the two consecutive crests. Wave height and period criteria are set to avoid detecting small oscillations (with amplitude <0.1 m and period <\(T_p/4\)).

4. Results and discussion

In this section, the different reconstruction methods presented above are applied to LS1 and LS2 dataset and further compared (see Tables 1 and 2). We first assess each method in near-breaking conditions. These conditions are characterized by the presence of nonlinear waves for which the validity of linear reconstruction methods to recover individual wave characteristics is questionable. Then, the ability of each method to recover waves within wave groups which contain highly nonlinear and extreme waves is addressed. Finally, we present a wave-by-wave analysis over the whole dataset.

4.1. Near-breaking conditions

In this subsection, we focus on a 10-min time series from LS1 characterized by highly nonlinear waves, i.e. waves just before the onset of breaking (see the blue point at the first outer surf zone limit of LS1 in Fig. 6; \(h_0 = 2.25 \text{ m}; \mu = 0.075\)). This time series is characterized by a peak wave period of 11.5 s, a significant wave height of 0.71 m and a maximum individual wave height of 1.4 m. The latter yields a maximum nonlinearity parameter \(\varepsilon\) of 0.31 corresponding to strong in-situ nonlinearities.

4.1.1. Linear methods and semi-empirical transfer function

Surface elevation energy density spectra computed from the TFM with different high-frequency tail corrections and the semi-empirical TFM (see Table 1) are presented in Fig. 7. Here, the nonlinear cutoff frequency \(f_c\) is set at 0.32 Hz which corresponds to frequency up to the third harmonic (around 0.28 Hz). As explained in Section 2, the cutoff frequency associated with spectral reconstruction methods is optimized. Indeed, it is set by comparing the wave energy reconstructed from the TFM - no cutoff (\(\xi_{nc}\)) and the true wave energy (\(\xi_m\)). \(f_c\) is taken at the frequency for which the TFM correction starts exceeding the measured wave energy. Again, results are very sensitive to \(f_c\). Depending on its value, the computed wave surface elevation can be significantly altered, which will be addressed at the end of this section.

As expected, \(\xi_{nc}^{\text{1982}}\) correctly reproduces the low-frequency spectrum as well as the first harmonic (around 0.09 Hz) but strongly underestimates the energy of all subsequent harmonics. The semi-empirical TFM, \(\xi_{st}\), provides a good estimate of wave energy up to the second harmonic (around 0.18 Hz) but then slowly starts underpredicting all the subsequent harmonics as well. For \(f < f_c\), the TFM - sharp cutoff, \(\xi_{sh}^{\text{1982}}\), (equivalent to \(\xi_{sh}^{\text{1982}} = \xi_{st}^{\text{1982}}\)) properly reproduces the energy spectrum compared to \(\xi_m\).

For \(f > f_c\), \(\xi_{sh}^{\text{1982}}\) (equivalent to \(\xi_{sh}^{\text{1982}}\)) strongly underestimates the energy by two to three orders of magnitude at the highest frequencies. The TFM - Jonswap, \(\xi_j\), is able to reproduce the high-frequency tails’ slope

![Fig. 7. Surface elevation energy density spectra E(f). AST measurements: \(\xi_m\) (black line); hydrostatic reconstruction: \(\xi_{sh}^{\text{1982}}\) (blue line); TFM - sharp cutoff: \(\xi_{sh}\) (green line); TFM - linear cutoff: \(\xi_{st}\) (magenta line); TFM - steady cutoff: \(\xi_{st}^{\text{1982}}\) (red line); TFM - Jonswap: \(\xi_j\) (red dashed line); TFM - no cutoff \(\xi_{nc}\) (black dashed line); semi-empirical TFM: \(\xi_s\) (yellow line); see the associated equations in Table 1. \(f_c\) = 0.32 Hz (vertical black dotted line). The spectra have been averaged over 1/66 Hz. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

but does not reconstruct any harmonics. In the other hand, both the TFM - linear cutoff and the TFM - steady cutoff, \(\xi_{nc}\) and \(\xi_{st}\), respectively, improve \(\xi_{sh}\) by correctly recovering one extra harmonic (fourth harmonic around 0.36 Hz), even though the energy is slightly underestimated. Unlike \(\xi_{nc}\), that keeps correcting \(\xi_{sh}\) over all frequencies, \(\xi_{nc}\) fades into \(\xi_{sh}\) around 0.7 Hz.

The relative error of the spectral significant wave height \(H_{\text{max}}\) = 4\(\sqrt{\xi_m}\) (where \(m_0\) is the zero-th spectral moment calculated between 0 and 1 Hz), the maximal crest elevation (\(\xi_m\)) and the skewness parameter \(S_x = (\xi_m^3) / (\xi_m^2)^{3/2}\) (where \(<, >\) is the time-averaging operator) are computed for each reconstruction formula (see Table 3). In terms of \(H_{\text{max}}\), all TFM as well as the semi-empirical TFM are significantly better than \(\xi_{nc}^{\text{1982}}\) (equivalent to pressure measurements) and lead to reasonable \(H_{\text{max}}\) error (<7.4 %) which is in line with the literature (e.g. Guza and Thornton, 1980; Bishop and Donelan, 1987). \(\xi_{nc}\) provides the same \(H_{\text{max}}\) as \(\xi_{nc}\). Both \(\xi_{nc}\) and \(\xi_{st}\) are better than \(\xi_{nc}\) by roughly 2 %. As \(\xi_{nc}\) strongly underestimates the fourth and fifth harmonics (around 0.36 and 0.45 Hz in Fig. 7), the computed \(H_{\text{max}}\) error is slightly higher than all other linear reconstructions. Among all reconstructions, \(\xi_{st}\) has the lowest \(H_{\text{max}}\) error.

The same trend is observed for temporal parameters (\(\xi_{nc}\) and \(S_x\)). In terms of these parameters, \(\xi_{nc}\) performs roughly the same as \(\xi_{nc}\). The TFM is slightly improved using the linear cutoff and the steady cutoff approaches (\(\xi_{nc}\) and \(\xi_{st}\), respectively). Nonetheless, \(\xi_{nc}\), which gives the best agreement with \(\xi_{nc}\), still considerably underestimates both \(\xi_{nc}\) and \(S_x\) by 26.5 % and 37.2 %, respectively (see Table 3).

For the sake of clarity, we only display in Fig. 8 the water depth time series reconstructed from the TFM - sharp cutoff and the TFM - steady cutoff (the latter giving the best results among all linear reconstructions). In line with the errors shown in Table 3, both

Fig. 8. Water depth time series of a wave group. AST measurements: \( h_0 + \zeta_m \) (black points); hydrostatic reconstruction: \( h_0 + \zeta_m \text{SH} \) (blue line); TFM - sharp cutoff: \( h_0 + \zeta_{\text{ST}} \text{SH} \) (green line); TFM - steady cutoff: \( h_0 + \zeta_{\text{ST}} \) (red line); see the associated equations in Table 1. \( f_c = 0.32 \text{Hz} \) and \( h_0 = 2.25 \text{m.} \) (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

reconstructions are able to recover the smallest waves but they strongly underestimate the peaked and skewed shape of the highest waves within the group, even though \( \zeta_{\text{SH}} \) slightly improves the reconstructed crest elevation compared to \( \zeta_{\text{ST}}. \)

In most studies involving surface elevation recovery from pressure sensors, the rationale for choosing a particular \( f_c \) value is often unclear. To assess the cutoff frequency sensitivity, we set \( f_c \) at 0.6 Hz, which corresponds to the highest value found in the literature. Fig. 9 shows the effect on the wave energy spectrum. With such cutoff frequency, the section of the wave energy between 0.32 Hz and 0.6 Hz computed from \( \zeta_{\text{SH}} \) is overestimated. This drawback is strengthened for \( \zeta_{\text{L}} \) and \( \zeta_{\text{ST}} \) because these methods (Eqs. (22)-(24)) already filter the high-frequency tail. In Fig. 9, this is particularly noticeable for \( \zeta_{\text{ST}} \) which overestimates the harmonic around 0.61 Hz. As the reconstructed energy is higher, the \( H_{\text{max}} \) error is much lower (1.4 % for \( \zeta_{\text{SH}} \) and 0.4 % for \( \zeta_{\text{ST}} \)).

As shown in Fig. 10, due to the energy overestimation, the crest elevation of each wave is artificially enhanced and the reconstructed time series is affected by stronger parasite oscillations compared to \( f_c = 0.32 \text{Hz}. \) These oscillations severely transform the shape of the surface wave elevation, particularly within the back face and the trough of the highest waves (see for instance at \( t = 236 \) and 252 s in Fig. 10).

These results show that the classical TFM predicts the significant wave height with reasonable accuracy even when waves are nonlinear (see \( H_{\text{max}} \) in Table 3). The different high-frequency tail correction methods associated with the TFM (see Table 1) lead to lower \( H_{\text{max}} \) error by artificially amplifying the high-frequency wave spectrum. However, in terms of individual wave characteristics, all linear reconstruction methods reviewed here show similar skill. They significantly underestimate the crest elevation of the highest waves as well as its skewed shape. In the following, only the TFM with a sharp high-frequency tail correction (see TFM - sharp cutoff in Table 1), hereafter referred to as \( \zeta_{\text{L}} \), is used for systematic comparison with nonlinear methods.

4.1.2. Nonlinear methods

Reconstructed surface elevation energy and time series from each nonlinear method (except for \( \zeta_{\text{SH}} \) for the sake of clarity) are presented in Figs. 11–13. As explained in Section 3.2, pressure time series (equivalent to \( \zeta_{\text{SH}} \) Eq. (3)) were low-pass filtered to remove instrumental noise. The cutoff frequency associated with this filter is the cutoff frequency \( f_{\text{c,noise}} \) set to 1 Hz here. This cutoff frequency is applied to compute the weakly-dispersive methods \( \zeta_{\text{L}} \) and \( \zeta_{\text{NC}} \). \( f_{\text{c,noise}} \) is much higher than the nonlinear cutoff frequency, used for the fully-dispersive methods (\( f_{\text{c,noise}} = 0.32 \text{Hz}. \) This makes the fully-dispersive methods much more restrictive than the weakly-dispersive methods and the high-frequency

Fig. 9. Surface elevation energy density spectra \( E(f) \). AST measurements: \( \zeta_m \) (black line); hydrostatic reconstruction: \( \zeta_{\text{SH}} \) (blue line); TFM - sharp cutoff: \( \zeta_{\text{ST}} \text{SH} \) (green line); TFM - linear cutoff: \( \zeta_{\text{L}} \) (magenta line); TFM - steady cutoff: \( \zeta_{\text{ST}} \) (red line); TFM - Jonswap: \( \zeta_{\text{J}} \) (red dashed line); TFM - no cutoff \( \zeta_{\text{NC}} \) (black dashed line); semi-empirical TFM: \( \zeta_{\text{SE}} \) (yellow line); see the associated equations in Table 1. \( f_c = 0.6 \text{Hz} \) (vertical black dotted line). The spectra have been averaged over 1/66 Hz. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

Fig. 10. Water depth time series of a wave group. AST measurements: \( h_0 + \zeta_m \) (black points); hydrostatic reconstruction: \( h_0 + \zeta_{\text{SH}} \) (blue line); TFM - sharp cutoff: \( h_0 + \zeta_{\text{ST}} \text{SH} \) (green line); TFM - steady cutoff: \( h_0 + \zeta_{\text{ST}} \) (red line); see the associated equations in Table 1. \( f_c = 0.6 \text{Hz} \) and \( h_0 = 2.25 \text{m.} \) (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)
and regarding spectral wave parameters (\(\zeta\); weakly-dispersive linear reconstruction: \(\zeta_{\text{SL}}\) (magenta line); weakly-dispersive nonlinear reconstruction: \(\zeta_{\text{SNL}}\) (red line); heuristic reconstruction: \(\zeta_{\text{HE}}\) (yellow line); see the associated equations in Table 2). \(\zeta_{\text{HE}}\) is the sign for both methods (33) are used. \(H_{\text{0}}\) (blue line); weakly-dispersive nonlinear reconstruction: \(\zeta_{\text{SNL}}\) (red line); heuristic reconstruction: \(\zeta_{\text{HE}}\) (yellow line); see the associated equations in Table 2. \(\zeta_{\text{HE}}\) is the sign for both methods (33) are used.

The ability of the weakly-dispersive methods to calculate the energy distribution is reflected in the surface elevation time series (see Figs. 12 and 13). Compared to \(\zeta_{\text{HE}}\) and \(\zeta_{\text{SL}}\), the weakly-dispersive reconstructions do not result in any parasite oscillation (see Fig. 12). \(\zeta_{\text{SNL}}\) reproduces very well the wave crests even for the highest wave with an error of 7.1 \% (see Table 4). The wave shape is also properly recovered especially the steep slope of the front and back face of the highest wave (see the zoom of the highest wave in Fig. 13), which translates into the lowest skewness error compared to \(\zeta_{\text{HE}}\) and \(\zeta_{\text{SL}}\).

Among all reconstruction methods presented in this work, \(\zeta_{\text{SNL}}\) is found to provide the best agreement with the measured surface elevation \(\zeta_{\text{m}}\) regarding spectral wave parameters (\(H_{\text{0}}\)) and more importantly regarding individual wave characteristics (\(\zeta_{\text{c,max}} \) and \(\zeta_{\text{L}}\)). In the wave groupiness section below, only the commonly-used transfer function method \(\zeta_{\text{TFM}}\) (TFM - sharp cutoff) and the weakly-dispersive nonlinear method \(\zeta_{\text{SNL}}\) are used.

### 4.1.3. Wave groupiness

Earlier studies have proven that the presence of wave groups and the infragravity wave generation are both related (Longuet-Higgins and Stewart, 1962; Symonds et al., 1982). It is also well known that infragravity waves can result in coastal erosion and inundation events during extreme wave conditions (Roelvink et al., 2009; Baumann et al., 2017; Bertin et al., 2018). Well predicting wave groupiness is then of paramount importance for coastal applications. Along with the measured infragravity waves, Fig. 14a shows the measured wave envelope computed as the low-pass-filtered Hilbert transform of the short-wave signal (Battjes et al., 2009), with the corresponding time series of reconstructed dimensionless crest and trough elevation shown in Fig. 14b. The dimensionless crest elevation,

\[
\xi = \frac{\zeta_{\text{c}}}{H_{\text{m}}}
\]

(33) can be considered as a local nonlinearity parameter (where \(\zeta_{\text{c}}\) is the crest elevation of each individual wave). Fig. 14b shows the time series of both measured and reconstructed \(\xi\) (\(\xi_{\text{HE}}\), \(\xi_{\text{L}}\), and \(\xi_{\text{SNL}}\), respectively). \(\xi_{\text{HE}}\) has an average value of 0.16 but peaks at much higher values (between 0.35 and 0.51) within the three wave groups (see at \(t = 250\) s, 400 s and 760 s in Fig. 14b). Waves within these groups are highly nonlinear and also meet the following criteria:

\[
\frac{\zeta_{\text{m}}}{H_{\text{0}}} > 1.25
\]

(34) where \(H_{\text{0}}\) is the significant wave height, here defined as four times the standard deviation of the surface elevation. Criteria 34 is commonly used for identifying extreme waves (Dysthe et al., 2008). These highly nonlinear extreme waves also correspond to waves where the SNL correction is the most skillful compared to the linear (TFM) correction in terms of dimensionless crest elevations. The average of the highest one-tenth dimensionless crest elevations (\(\xi_{\text{c,1/10}}\)) is underestimated by 30.0 \% and by 2.5 \% for the linear and SNL method, respectively.

By visually checking images recorded from the video system, the most nonlinear wave over this 10-min time series ((\(\xi_{\text{c,1/10}}\max = 0.51\)) is just before the onset of breaking. Over the whole dataset, the highest value of \(\xi_{\text{c,1/10}}\) is 0.53 outside of the surf zone, corresponding to a wave that is even closer to breaking. Hence, well predicting these waves is crucial for estimating the break point position which is a key parameter to many coastal applications and wave propagation models. At the

Fig. 12. Water depth time series of a group of waves. AST measurements: \(\zeta_{\text{m}}\) (black points); hydrostatic reconstruction: \(\zeta_{\text{HE}}\) (blue line); weakly-dispersive linear reconstruction: \(\zeta_{\text{L}}\) (magenta line); weakly-dispersive nonlinear reconstruction: \(\zeta_{\text{SNL}}\) (red line); heuristic reconstruction: \(\zeta_{\text{HE}}\) (yellow line); see the associated equations in Table 2. \(\zeta_{\text{HE}}\) is poorly computed in the highest frequencies as it relies on the TFM. In terms of \(H_{\text{0}}\), \(\zeta_{\text{SNL}}\) has the lowest error of all reconstruction methods reviewed in this article (see Table 4).

Fig. 13. Water depth time series of the highest wave. AST measurements: \(\zeta_{\text{m}}\) (black points); hydrostatic reconstruction: \(\zeta_{\text{HE}}\) (blue line); weakly-dispersive linear reconstruction: \(\zeta_{\text{L}}\) (magenta line); weakly-dispersive nonlinear reconstruction: \(\zeta_{\text{SNL}}\) (red line); heuristic reconstruction: \(\zeta_{\text{HE}}\) (yellow line); see the associated equations in Table 2. \(\zeta_{\text{HE}}\) is the sign for both methods (33) are used. \(H_{\text{0}}\) (blue line); weakly-dispersive nonlinear reconstruction: \(\zeta_{\text{SNL}}\) (red line); heuristic reconstruction: \(\zeta_{\text{HE}}\) (yellow line); see the associated equations in Table 2. \(\zeta_{\text{HE}}\) is the sign for both methods (33) are used.
Tables 3 and 4). However, at the scale of individual waves, the linear reconstruction fails to correctly recover the skewness parameter $\zeta_m$ as a function of the average nonlinear parameter $\epsilon_m$. The method gives slightly smaller errors for low $\epsilon_m$. As nonlinearities increase, the difference between both methods becomes stronger with SNL error varying around 5 to 10% while TFM error hovers around 15 to 25% for the highest $\epsilon_m$ (>0.14).

This pattern is strengthened for $\epsilon_m = 0.2$ (see Fig. 15b). For low $\epsilon_m$, the SNL method is better than the linear method by 3–5%. Both methods quickly deviate for moderate to strong nonlinearities. For the highest $\epsilon_m$, the SNL method is significantly better than the linear method by 13–28%.

In terms of $S_5$ (see Fig. 15c), the linear reconstruction fails to correctly describe the skew wave shape with a scattered $S_5$ error between 16.6% and 51.7% and an average error of 29.4%. Indeed, parasite oscillations induced by the cutoff can strongly modify the shape of the most nonlinear waves which worsen $S_5$ prediction. Unlike the linear method, the SNL method skillfully recovers the wave shape with a $S_5$ error systematically lower than 20% with an average of 8.5%.

**Fig. 15.** Relative error (% of (a) the root-mean-square crest elevation $\langle \zeta \rangle_{\text{RMS}}$, (b) the average of the highest one-tenth crest elevation $\langle \zeta \rangle_{1/10}$ and (c) the skewness parameter $S_5$ as a function of the average nonlinear parameter $\epsilon_m$. TFM - sharp cutoff $\zeta_m$ (blue circles); weakly-dispersive nonlinear reconstruction $\zeta_{\text{SNL}}$ (red circles); see the associated equations in Tables 1 and 2 for the SNL method. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

In this section, a wave-by-wave analysis of the entire dataset is performed. For each time series, relative errors for both linear and SNL reconstruction methods are computed in terms of three parameters: the root-mean-square crest elevation $\langle \zeta \rangle_{\text{RMS}}$, the average of the highest one-tenth crest elevation $\langle \zeta \rangle_{1/10}$ and the skewness parameter $S_5$. Those are represented in Fig. 15 as a function of the average nonlinear parameter $\epsilon_m$ computed as:

$$\epsilon_m = \frac{(H_{\text{rms}})_{\text{RMS}}}{H_0}$$

where $(H_{\text{rms}})_{\text{RMS}}$ is the measured root-mean-square wave height. AST measurements allow to detect the wave crest of all individual waves of the entire dataset. Of note, in a limited number of 10-min time series some surface elevation was missing locally in the front faces. For these time series, $S_5$ could not be calculated properly.

For the linear reconstruction, the relative error $\langle \zeta \rangle_{\text{RMS}}$ increases with increasing $\epsilon_m$. For low $\epsilon_m$ (<0.10), the RMS crest elevation error (see Fig. 15a) is less than 10%. The results of SNL method are roughly equivalent to those of the linear reconstruction, even though the SNL reconstruction methods are computed in terms of three parameters: the root-mean-square crest elevation $\langle \zeta \rangle_{\text{RMS}}$, the average of the highest one-tenth crest elevation $\langle \zeta \rangle_{1/10}$ and the skewness parameter $S_5$. These extreme waves correspond to 0.7% detected individual waves for both reconstruction methods (see Fig. 16a and b).

However, for higher values of $\epsilon_m$ (>0.25), the two methods show different results. The linear method considerably underestimates the highest one tenth dimensionless crest elevation (average error of 20.3%; see Fig. 16c) while the weakly-dispersive nonlinear method is able to recover the crests of the most nonlinear waves (average error of 6.9%; see Fig. 16d). Blue crosses represent waves that meet the extreme wave criteria (Eq. (34)). These extreme waves correspond to 0.7% of all detected waves and correspond to some of the most nonlinear waves of our dataset (0.30 < $\epsilon_m$ < 0.53), which are correctly recovered by SNL, only. The linear reconstruction underestimates the dimensionless crest elevation of the detected extreme waves with an average error and a maximum error of 27.9% and 36.6%, respectively, against 5.4% and 16.7% for the SNL method.

**Fig. 14.** (a) Measured wave envelope (black line) and measured infragravity surface elevation (black dashed line). (b) Dimensionless wave crests (filled circles) and troughs (empty circles) elevation. AST measurements: $\zeta_m$ (black circles); TFM - sharp cutoff $\zeta_m$ (blue circles); weakly-dispersive nonlinear reconstruction $\zeta_{\text{SNL}}$ (red circles); see the associated equations in Tables 1 and 2. For low $\epsilon_m$ (<0.10), the RMS crest elevation error (see Fig. 15a) is less than 10%. The results of SNL method are roughly equivalent to those of the linear reconstruction, even though the SNL reconstruction methods are computed in terms of three parameters: the root-mean-square crest elevation $\langle \zeta \rangle_{\text{RMS}}$, the average of the highest one-tenth crest elevation $\langle \zeta \rangle_{1/10}$ and the skewness parameter $S_5$. These extreme waves correspond to 0.7% detected individual waves for both reconstruction methods (see Fig. 16a and b).

However, for higher values of $\epsilon_m$ (>0.25), the two methods show different results. The linear method considerably underestimates the highest one tenth dimensionless crest elevation (average error of 20.3%; see Fig. 16c) while the weakly-dispersive nonlinear method is able to recover the crests of the most nonlinear waves (average error of 6.9%; see Fig. 16d). Blue crosses represent waves that meet the extreme wave criteria (Eq. (34)). These extreme waves correspond to 0.7% of all detected waves and correspond to some of the most nonlinear waves of our dataset (0.30 < $\epsilon_m$ < 0.53), which are correctly recovered by SNL, only. The linear reconstruction underestimates the dimensionless crest elevation of the detected extreme waves with an average error and a maximum error of 27.9% and 36.6%, respectively, against 5.4% and 16.7% for the SNL method.
Eq. (31) was found to be essential to accurately recover the highest waves, especially in the shoaling zone (μ > 0.3) and mean water depth \( h_0 \). \( \mu < 0.3 \) corresponds to weakly-dispersive regime (horizontal dotted line) and \( \mu > 0.3 \) corresponds to fully-dispersive regime (vertical dotted line).

An accurate direct measurement of the surface elevation of fully-dispersive waves outside the surf zone and broken waves inside the surf zone is still required for identifying two thresholds: one for using \( \zeta_{\text{SNL}} \) and one for using \( \zeta_{\text{TFM}} \) or \( \zeta_{\text{SNL}} \) and one for using \( \zeta_{\text{SNL}} \) or \( \zeta_{\text{SNL}} \) (see Fig. 18).

5. Conclusion

We have applied and compared different methods to reconstruct the surface elevation from pressure measurements in case of irregular weakly-dispersive waves (μ < 0.2) propagating outside the surf zone (\( h_0 < 4 \) m). The commonly-used transfer function method (TFM) was found to give a reliable estimate of the significant wave height (\( H_{\text{Sn}} \)) with error not exceeding 7% in near-breaking conditions which feature highly nonlinear waves. However, this method requires the use of a cutoff frequency which restricts the reconstruction of the most nonlinear waves. The TFM solution is very sensitive to the value of this cutoff frequency, especially the reconstructed surface wave elevation. The latter can be affected by the presence of parasite oscillations that strongly alter the shape of the highest waves. Associated with the TFM, several high-frequency tail correction procedures were tested and found to slightly improve \( H_{\text{Sn}} \) prediction. Nonetheless, these procedures still fail to describe the energy distribution in the highest frequencies leading to an underestimation of the crest elevation of the highest wave and the skewness parameter. On the contrary, the recently developed weakly-dispersive nonlinear reconstruction method (SNL) was found to correctly reproduce the wave spectrum over a large number of harmonics which allows an accurate estimation of the peaked and skewed shape of the highest waves. More importantly, unlike the TFM, this method is able to recover the most nonlinear waves within wave groups. Some of these waves can be characterized as extreme waves and are still accurately predicted by the SNL method (average relative error of 5.4%) compared to the TFM (average relative error of 27.9%). Well predicting these waves is essential for many coastal applications, in particular those that require a correct estimation of the highest waves such as studies on wave submersion, but also for predicting the break point position which is crucial for the calibration and the validation of wave propagation models.

Acknowledgements

The Ph.D. thesis work of A. Mouragues is cofunded by a DGA-Région Nouvelle Aquitaine scholarship. This study has received financial support from Région Nouvelle Aquitaine (contract n° 2017-1R20107) and was carried out as part of the project MPEELS (contract n° 18CP05), performed under the auspices of the DGA, and led by SHOM. The authors wish to thank all those who contributed to the field experiment at La Salie Beach: Detandt G., Bonneton N., Dubarbier B. and Poncet P.A.
